1 Assignment 1

1.1 Question 1.1 (2 points)

For $\alpha = 2$ we define $M \geq \frac{f(x)}{g(x)} = \frac{\beta^2}{\lambda} \frac{x}{e^{x(\beta-\lambda)}}$.

Using the hint and recognizing $\gamma = \beta - \lambda$ we have two cases.

Case 1: $\gamma < 1$, then $\max_x \frac{x}{e^{(\gamma x)}} \Rightarrow \infty$. So M would be infinity which is not feasible.

Case 2: $\gamma \geq 1$, then $\gamma = \beta - \lambda = 1 \Rightarrow \lambda = \beta - 1$.

So $M = \frac{\beta^2}{\lambda} = \frac{\beta^2}{\beta-1}$ and with $\beta = 2$ we get $M = 4$.

1.2 Question 1.2 (5 points)

The following function implements the Acceptance-Rejection-Sampling.

```
#####  
# Assignment 1.2  
#####  
  
acceptance_rejection_sampling = function(n, alpha = 2, beta = 2) {  
  
  M = (beta^2)/(beta - 1)  
  lambda = beta - 1  
  
  rs = c()  
  rs_rejected = c()  
  
  while (length(rs) < n) {  
    # Take a random sample from our proposal (x-axis)
```

```

z = rexp(n = 1, rate = lambda)

# Take a uniform, thus a random y value
u = runif(n = 1, min = 0, max = M * dexp(z, lambda))

# Check in which region this on lies
if (u <= dgamma(z, shape = alpha, rate = beta)) {
  rs = c(rs, z)
}

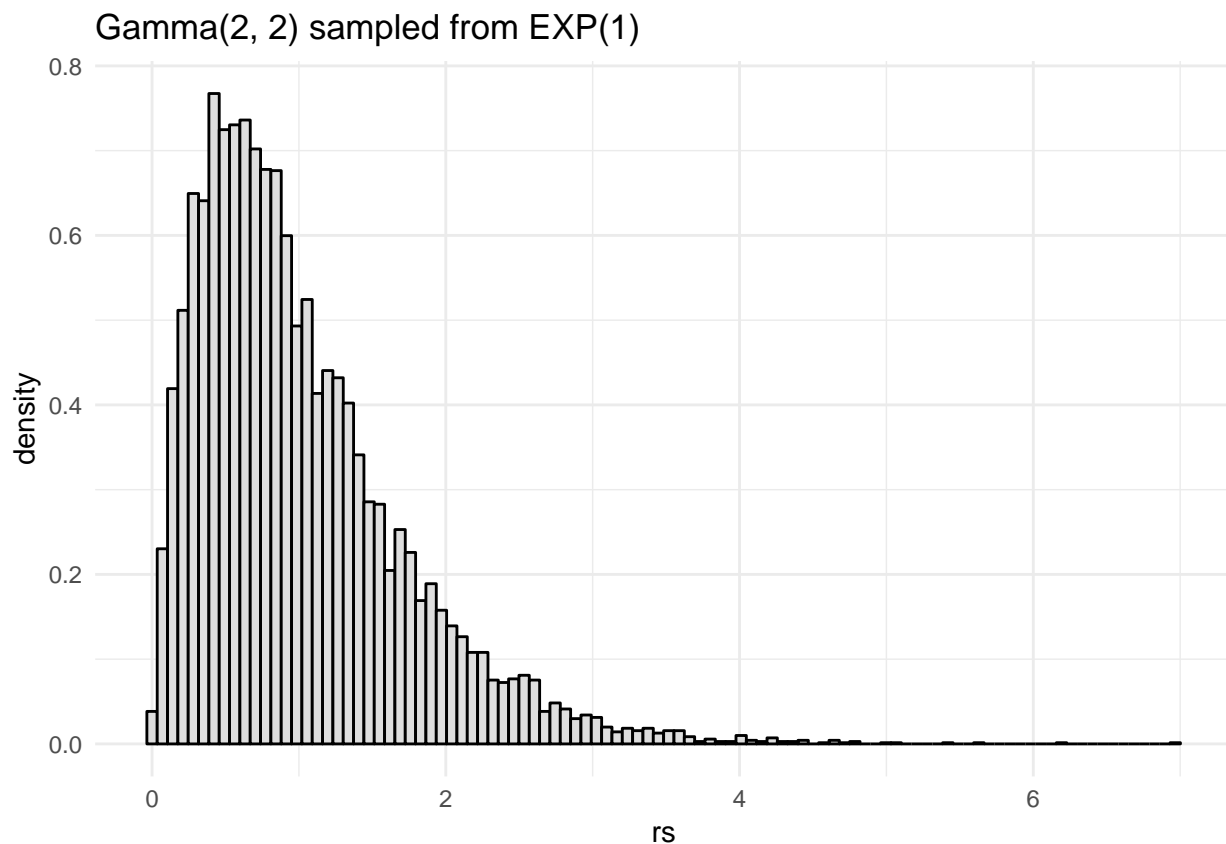

else {
  rs_rejected = c(rs_rejected, z)
}
}

return(list(rs, rs_rejected))
}

ars_results = acceptance_rejection_sampling(10000)

```

The histogram of the drawn samples can be seen in the following figure:

The expected rejection rate is given by $1 - \frac{1}{M}$ and here given by 0.75.

The observed rejection rate is given by $\frac{\text{rejected}}{\text{accepted} + \text{rejected}}$ and here given by 0.7496871.

Question: Compare (graphically and using relevant statistics) your simulated samples with the true Gamma

distributions. Provide appropriate plots and comments.

Answer: We can see that the proposal envelops the target distribution but has a large rejection rate. That's why we reject 0.7496871 which is given by $\frac{\text{rejected}}{\text{accepted} + \text{rejected}}$.

If we compare the real `Gamma(2, 2)` with the histogram of our samples, they look almost identical-

In the exam a plot of a histogram of the real `Gamma(2, 2)` should be shown as well. Also different parameters should be used.

1.3 Question 1.3 (3 points)

The sampling function is given by:

$$d(x, \alpha = 2, \beta = 2) = 4xe^{-2x}$$

Note that $\text{Gamma}(\alpha) = (\alpha - 1)!$

We then identify:

$$g(x) = \frac{1}{4}x^3$$

So we simply put our drawn samples into $g(x)$ and calculate the mean.

```
#####  
# Assignment 1.3  
#####  
  
g = function(x) return(1/4 * x^3)  
  
mean(g(ars_results[[1]]))  
  
## [1] 0.7531224
```

2 Assignment 2

```
#####  
# Assignment 2  
#####  
  
f = function(x) {  
  return(-x * sin(10 * pi * x) + 1)  
}
```

The function to analyse looks like this.

2.1 Question 2.1 (2 points)

The helper functions look like this.

```
#####
# Assignment 2.1
#####

to_base_10 = function(v) {
  return(Reduce(function(s,r) {s*2+r}, v))
}

transform_to_interval = function(u, a = -1, b = 2, m = 15) {
  return(a + u * ((b - a)/(2^m - 1)))
}

chrom_to_x = function(chromosome) {
  return(transform_to_interval(to_base_10(chromosome)))
}

chrom_to_y = function(chromosome) {
  return(f(transform_to_interval(to_base_10(chromosome))))
}
```

2.2 Question 2.2 (3 points)

```
#####  
# Assignment 2.2  
#####  
  
tournament_selection = function(population) {  
  
  # Select fighting partners / groups  
  fighters = sample(1:nrow(population), 4)  
  
  # Get their values  
  fighter_A = population[fighters[1],]  
  fighter_B = population[fighters[2],]  
  fighter_C = population[fighters[3],]  
  fighter_D = population[fighters[4],]  
  
  # Let them fight, group A  
  if (chrom_to_y(fighter_A[2:length(fighter_A)]) <  
      chrom_to_y(fighter_B[2:length(fighter_B)])) {  
    winner_group_A = fighter_A  
    loser_group_A = fighter_B  
  }  
  else {  
    winner_group_A = fighter_B  
    loser_group_A = fighter_A  
  }  
  
  # Let them fight, group B  
  if (chrom_to_y(fighter_C[2:length(fighter_C)]) <  
      chrom_to_y(fighter_D[2:length(fighter_D)])) {  
    winner_group_B = fighter_C  
    loser_group_B = fighter_D  
  }  
  else {  
    winner_group_B = fighter_D  
    loser_group_B = fighter_C  
  }  
  
  # Return them, first two are winners, last two are loser  
  results = data.frame()  
  results = rbind(results, winner_group_A)  
  results = rbind(results, winner_group_B)  
  results = rbind(results, loser_group_A)  
  results = rbind(results, loser_group_B)  
  
  return(results)  
}
```

Question: Sometimes one varies this tournament selection and the best individual is chosen with a certain probability lesser than 1. Can you provide a motivation for this?

Answer: If we have some knowledge about the function, that it's mostly monotonic, it might sense to put more emphasis on the best individual. The tournament selection might work better if a lot of individuals get

stuck, like here, in local minima. Thus in this case the best individual (with a probability lesser than 1) might work better.

2.3 Question 2.3 (5 points)

```
#####  
# Assignment 2.3  
#####  
  
# Generate a population of size n with m digits as genes  
generate_population = function(n, m = 15) {  
  
  population = data.frame()  
  
  for (i in 1:n) {  
    individual = c(i, ifelse(round(rnorm(m, mean = 0, sd = 1)) > 0, 1, 0))  
    population = rbind(population, individual)  
  }  
  
  colnames(population) = c("index", as.character(seq(from = 1, to = m, by = 1)))  
  return(population)  
}  
  
# Does a crossover where the children take one half of each parent  
crossover = function(chrom_A, chrom_B) {  
  chrom_A = unlist(chrom_A)  
  chrom_B = unlist(chrom_B)  
  
  cut = round(length(chrom_A)/2)  
  
  child_A = c(chrom_A[2:cut], chrom_B[(cut+1):length(chrom_B)])  
  child_B = c(chrom_B[2:cut], chrom_A[(cut+1):length(chrom_B)])  
  
  return(list(child_A, child_B))  
}  
  
# Mutates a single bit based on prob  
mutate_with_prob = function(x, prob) {  
  if (runif(n = 1) < prob) {  
    return(ifelse(x == 0, 1, 0))  
  }  
  else {  
    return(x)  
  }  
}  
  
# Mutates on average prob genes, each gene has a prob of prob/length to mutate  
mutate = function(chrom, prob = 0.05) {  
  chrom = unlist(chrom)  
  # To get an average of 0.05 bits mutated  
  digit_prob = prob / length(chrom)  
  chrom[2:length(chrom)] = sapply(chrom[2:length(chrom)], mutate_with_prob, prob)  
  return(chrom)  
}
```

```

}

# Helper function to get the best individual from a population
get_best_individual = function(population) {
  index_best = which.min(apply(population[,2:ncol(population)], 1, chrom_to_y))
  return(population[index_best,])
}

# Use all pre defined methods to actually implement the genetic algorithm
genetic_algorithm = function(population_size = 55, mutprob = 0.05, runs = 100) {

  # Generate population
  population = generate_population(population_size)

  best_individual = get_best_individual(population)

  best_individual_iteration = 0

  for (i in 1:runs) {

    # Selection
    fighters = tournament_selection(population)

    # Create children of winners
    children = crossover(fighters[1,], fighters[2,])

    # Mutate the new individuals
    children[[1]] = mutate(children[1], prob = mutprob)
    children[[2]] = mutate(children[2], prob = mutprob)

    # Replace the losers with the new winners
    population[fighters[3,1], 2:ncol(population)] = children[[1]]
    population[fighters[4,1], 2:ncol(population)] = children[[2]]

    # Save the overall best individual
    current_best = get_best_individual(population)
    if (chrom_to_y(current_best[2:length(current_best)]) <
        chrom_to_y(best_individual[2:length(best_individual)])) {
      best_individual = current_best
      best_individual_iteration = i
    }
  }

  return(list(best = best_individual, population = population,
             iteration = best_individual_iteration))
}

```

The example call for `mutprob = 0.0077` looks like this.

```

results0077 = genetic_algorithm(population_size = 55, mutprob = 0.0077, runs = 100)
print(results0077$best)

```

```

##      index 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15
## 53      53 1 1 1 0 0 0 1 0 1 0 0 0 1 0 1

```

```
print(results0077$iteration)
```

```
## [1] 0
```

```
mutprob = 0.0077
```

The example call for `mutprob = 0.5` looks like this.

```
results05 = genetic_algorithm(population_size = 55, mutprob = 0.5, runs = 100)
print(results05$best)
```

```
##   index 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15
## 5      5 1 1 1 1 0 1 0 0 0 0 1 0 1 1 1
```

```
print(results05$iteration)
```

```
## [1] 17
```

Question: At which generation was the best value found?

Answer: The best value for `mutprob = 0.077` was found in iteration 0 and the best value for `mutprob = 0.5` was found in iteration 17.

Question: Was the minimum found?

Answer: For `mutprob = 0.077` no, for `mutprob = 0.5` yes. If we count in the error the encoding does, then `mutprob = 0.5` also did not find the minimum, but it found (probably) the best one the encoding of 15 bits could do.

Question: Can you explain the observed behaviour, especially when taking into account the mutation probability?

Answer: The mutation probability increases the randomness, which means how the space is being explored. A really high mutation makes the discovery mostly random, while a small one relies more on the characteristics of the parents. Here the function has a lot of *traps* which means relying on the parents is misleading. This means a higher mutation probability suits better for the problem we have here, which could change for other functions. A good way would be having a high mutation rate in the beginning of the algorithm and slowly decreasing on towards the end of the iterations, thus changed from global search to local search.
